

## **CLOCKING SCHEME FOR AN ALGORITHMIC ANALOG-TO- DIGITAL CONVERTER**

### **Abstract**

[91] An algorithmic analog-to-digital converter (ADC) includes a sample-and-hold  
5 circuit and an ADC processing unit operating in parallel and sharing a single operational  
amplifier. The ADC processing unit includes an MDAC with a switched capacitor  
topology and a sub-ADC. The ADC processing unit is clocked by an internal clock that  
is N times faster than the sample-and-hold clock. Each cycle is further sub-divided into  
two phases. During one phase the capacitors are coupled to a residue or sampled voltage  
10 provided by the MDAC, and during another phase the capacitor are coupled to a  
reference voltage determined by the switch control signals generated by the sub-ADC. A  
set of data bits is generated by the ADC processing unit during each ADC clock cycle.  
The N sets of data bits are added to generate the digital output stream. The internal  
clock, in turn, has a variable period allocating more time to the early operation phases  
15 where more accuracy is required and less time to the latter operation phases where less  
accuracy is required.
